Geochemical reactions

ABSTRACT

Geochemistry plays an important role when assessing the impact of CO₂ storage. Due to the potential corrosive character of CO₂, it might affect the chemical and physical properties of the wells, the reservoir and its surroundings and increase the environmental and financial risk of CO₂ storage projects in deep geological structures. An overview of geochemical and solute transport modelling for CO₂ storage purposes is given, its data requirements and gaps are highlighted, and its progress over the last 10 years is discussed. Four different application domains are identified: long-term integrity modelling, injectivity modelling, well integrity modelling and experimental modelling and their current state of the art is discussed. One of the major gaps remaining is the lack of basic thermodynamical and kinetic data at relevant temperature and pressure conditions for each of these four application domains. Real challenges are the coupled solute transport and geomechanical modelling, the modelling of impurities in the CO₂ stream and pore-scale modelling applications.

1. Introduction

Carbon capture and storage has been validated by the IPCC (2005) as part of a portfolio of measures to mitigate climate change, and pilot projects are multiplying around the world. In order for the technology to be deployed on a large-scale, its viability in terms of injectivity, the containment of the injected CO₂ and the long-term safety with respect to humans and the environment needs to be guaranteed. Geochemical reactions play an important role since, due to the corrosive character of CO₂, certainly once it is dissolved, they might affect the chemical and physical properties of the wells, the reservoir and its surroundings.

The scientific community identified this potential geochemical feedback on physical properties through highly coupled processes as soon as the technique emerged (e.g., Czernichowski-Lauriol et al., 1996; Gunter et al., 1997) and during the last 10 years geochemical and solute transport modelling made significant progress. It evolved from simple geochemical batch models assuming only interactions between CO₂ dissolved in brine and the rocks without taking into account any flow aspects, to three-dimensional fully coupled geochemical and flow models capable of capturing the geological complexity of the storage reservoir and its caprock(s). Currently, solute transport models are numerical codes that include the following processes: two (e.g., CO₂, brine) or three component (CO₂, oil, brine) density dependent flow, dissolution of CO₂, chemical speciation in brine, kinetic dissolution and/or precipitation of minerals of the host rock, and porosity change in the host rock as a consequence of these processes. For that, the equations of conservation of energy, of momentum, of mass and solute mass, together with constitutive laws are coupled in an implicit or explicit manner. A comprehensive review on solute transport modelling in general is given in Steefel et al. (2005) and consequently this will not be repeated here. This paper aims at giving an overview of solute transport modelling for CO₂ storage purposes, its underlying data requirements, its main pitfalls and how it can contribute in the future to ensure the viability of carbon storage.

First the importance of assessing geochemical impacts during CO₂ storage based on industrial, experimental and natural analogue evidence is demonstrated. Subsequently, different areas where geochemical and solute transport modelling is applied to investigate CO₂ storage (long-term integrity modelling, injectivity modelling, well integrity modelling and experimental modelling) are identified, together with their time and space scales of interest. A short history on coupled code development for CO₂ storage purposes is given. The requirements with respect to geochemical data and underlying understanding for a typical CO₂ storage site and their impact on the modelled results are

discussed. For each of the identified application domains its state of the art and development needs are reviewed. Finally, a summary and an outlook on future geochemical and solute transport modelling topics are given.

2. Importance of assessing geochemical impacts during CO₂ storage

Saline reservoirs in sedimentary basins seem to constitute one of the best targets for the storage due to their huge storage capacity. The formation waters in these reservoirs are characterised by salinities ranging from 5000 to >350,000 mg/L dissolved solids and present a weak interest in term of resources (in particular for potable use) because they most often contain dissolved species like toxic metals, organic and/or inorganic components and naturally occurring radioactive material (Kharaka and Hanor, 2007). The chemistry of these waters is the result of different hydrogeochemical processes like mixing, dissolution/precipitation of minerals like evaporites, bacterial activity and interactions with organics. The injection of CO₂ into such reservoirs constitutes an additional process influencing the chemistry of these waters and increasing the chemical reactivity of the system.

This is why the success of CO₂ storage and its worldwide development depends largely on the understanding of CO₂ behaviour in contact with water and minerals within reservoir for thousands of years.

Although generally pure CO₂ is assumed to be little reactive, once in contact with brine, it will form H₂CO₃, a weak acid that will almost immediately dissociate:

$$\text{H}_2\text{CO}_3 \rightarrow \text{H}^+ + \text{HCO}_3^-$$

This causes the pH of the brine to decrease and makes the brine corrosive to all materials in contact with it (well materials, rocks, pipelines, etc.). The impact of acidic fluids on rocks is illustrated by the damage to our historic buildings under the influence of acid rain. As shown hereafter, there is evidence that this acid attack due to dissolving CO₂ can have an important impact during CO₂ storage operations and, under particular circumstances, might determine the success or the failure of a carbon storage project.

Evidence of the impact of CO₂ acidification from the industry and in the field is multiple. The corrosive potential of CO₂ that contains only a fraction of water (wet CO₂) is well-known (Hesjevik et al., 2003) and becomes clear when transported through pipelines in that stainless steel pipelines are necessary to avoid corrosion damage. In practice it is not possible to transport wet CO₂ in low-alloy carbon steel pipelines because of its high corrosion rate (IPCC, 2005). Since water free storage reservoirs are not imaginable, this indicates that once injected, CO₂ is likely to dissolve and might induce

major geochemical reactions in the reservoir, the well or the overburden under particular circumstances that need to be evaluated accurately. Indirect evidence of geochemical reactions in the near well environment during industrial operations can be the occasional injectivity difficulties encountered during enhanced oil recovery (EOR) operations as described in Czernichowski-Lauriol et al. (1996), whereby traditionally a distinction was made between carbonate and sandstone reservoirs. Generally injectivity changes are poorly explained and vaguely attributed to multiphase flow, CO₂/oil interactions and/or CO₂/mineral interactions (Cailly et al., 2005). Seldom increased injectivity is observed. Hard evidence of the geochemical impacts of injecting CO₂ at the field scale is recently becoming available. Fluid and observation well samples from the CO₂ injection trial at the Frio formation indicated a significant pH drop, pronounced increases in alkalinity, as well as iron concentrations, indicating that almost immediately dissolution reactions take place in the injection area (Kharaka et al., 2006) due to acidification. Carbonate dissolution has also been identified to influence the brine composition in the reservoir as sampled in observation wells of the Weyburn project under the influence of CO₂ dissolution and H₂CO₃ dissociation (Wilson and Monea, 2004).

Laboratory experiments can further elucidate geochemical reactions caused by CO₂ acidification. Several experimental studies have been conducted with CO₂-saturated brine on reservoir material under various temperature and pressure conditions to evaluate the geochemical impact of CO₂ on the brine and the host rock. Where experiments have been conducted at relatively low temperatures, also due to their relatively short duration, apart from chemical brine changes, this has not generated strong dissolution or precipitation processes other than carbonate dissolution (e.g., Perkins and Gunter, 1995b; Gunter et al., 1997, 2000; Rochelle et al., 2004). Geochemical interactions are observed to be important at higher temperatures as described in Kaszuba et al. (2005), who performed experiments at 200 °C and 200 bar and reported important silicate precipitation next to carbonate precipitation, pointing out also that part of the geochemical interactions might be attributed to brine desiccation due to the H₂O dissolving in supercritical CO₂ (SC-CO₂). During flow-through experiments the formation of wormholes in limestone cores resulting from brine–CO₂ injection has been observed. This dramatically increases the permeability of the rock (Golfier et al., 2001) and illustrates the dissolving power of acid solutions.

Geochemical interaction caused by the presence of CO₂ in geological sequences where CO₂ is occurring naturally – *natural CO₂ storage analogues* – are particularly valuable since this illustrates the long-term impact of CO₂ on natural rocks that cannot be reproduced during experiments or field tests. Watson et al. (2004) observe that CO₂ induced precipitation reactions occur in fractures in cap rocks of natural analogues in Australia leading to a reduced injection capillary pressure measurements. The formation of minerals on fracture planes of natural CO₂ leakage paths, and carbonates and anhydrite in fractures and cracks has been documented by May (2005) and Fischer et al. (2006), respectively. The major geochemical precipitation reaction identified in a couple of natural reservoirs is the precipitation of dawsonite (examples in

Baker et al., 1995; Worden, 2006), an aluminium carbonate mineral that incorporates CO₂ and can make up to 17% of the reservoir (Moore et al., 2005). Chemical equilibrium seems not to be reached in some natural analogues, even when subjected to very long (geological) contact times (Haszeldine et al., 2005) suggesting that chemical equilibrium might not be the natural state of injected CO₂ during the whole duration of the storage period (thousands to hundreds of thousands of years).

3. What do we need to model and how long?

Geochemical and solute transport modelling has four main application domains when assessing the geochemical impact of CO₂ storage, each having its own spatial scale and timeframe of interest (Fig. 1) and therefore requiring an adapted modelling approach. An overview of the current state of the art of each of these applications is given in paragraph 6.

For *long-term integrity modelling* one aims to assess the ultimate fate of the CO₂ injected and its impact on physical properties. Four processes are distinguished: (i) *structural trapping*, which represents supercritical CO₂ trapped in the pore space as a buoyant immiscible fluid phase according to the heterogeneity of the storage zone lithology, (ii) *residual CO₂ trapping*, representing the supercritical CO₂ that is trapped in small pores and cannot be mobilized anymore, (iii) *dissolution trapping*, which represents CO₂ dissolved in the liquid phase (oil or brine), and (iv) *mineral trapping*, represents CO₂ incorporated into minerals due to chemical precipitation. Timescales of impact for these four types of trapping differ from one process to another (Fig. 2). The focus of this paper is on sedimentary reservoirs only: (i) depleted oil or gas reservoirs, and (ii) saline aquifers. Aquifers offer the advantage of having a larger volume and being the more abundant in

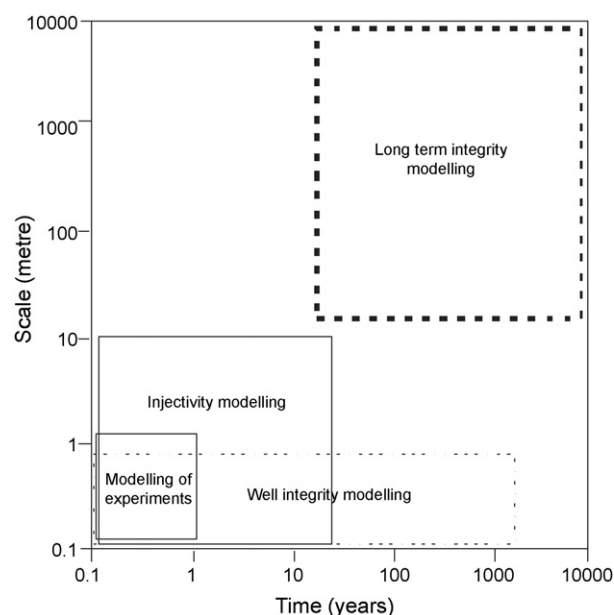

Fig. 1 – Application domains of geochemical and solute transport modelling relevant to CO₂ storage and their time and space scales.

Fig. 2 – Storage security depends on a combination of physical and geochemical trapping mechanisms. Over time, the physical process of residual CO₂ trapping and geochemical processes of solubility trapping and mineral trapping increase, most likely increasing storage security (IPCC, 2005).

the subsurface. Petroleum reservoirs offer the advantage of having the most advanced infrastructure for storage and monitoring of CO₂ (Holloway, 1997).

Structural trapping is the main trapping process occurring during the injection period (a couple of decades). The amount of supercritical CO₂ remaining in the storage site versus time is influenced in a significant way by its rate of dissolution. The brine containing the dissolved CO₂ is slightly denser than the original brine, inducing gravity-driven flow and convective fluid circulation if certain conditions for the onset of free convection are being met (Weir et al., 1996). Because of the difference between the density of the brine with and without dissolved CO₂, the mixing time t_{mix} required for the entire supercritical phase to dissolve depends mainly on the vertical permeability of the porous rock according to Ennis-King and Paterson (2003):

$$t_{\text{mix}} \approx \frac{\alpha L \mu}{k_v \Delta \rho g}$$

where α is the density ratio between the density of the gas phase CO₂ and the density as a dissolved phase (mass of CO₂ per volume of solution), L is the reservoir thickness, μ is the brine viscosity, k_v is the vertical permeability, $\Delta \rho$ is the density difference between brine with and without dissolved CO₂, and g is the gravity acceleration. Using typical parameters ($\mu = 5 \times 10^{-4}$ Pa s, $k_v = 10^{-15}$ to 10^{-14} m², $\Delta \rho = 10$ kg m⁻³, $L = 10$ m and $\alpha = 10$) for a likely storage site, values of t_{mix} range from 1600 to 16,000 years. Estimate of mixing time for the CO₂ gas bubble at Sleipner from a 3D model is about 7000 years for an average $k_v = 200$ mD (Lindeberg and Bergmo, 2003). Ennis-King and Paterson (2003) consider this result as

an under-estimate due to the dilution of the fingers as they propagate. Mixing by pure diffusion would be a much slower process with a time scale of $(\alpha L)^2/D$ where D is the diffusion coefficient. Mineral trapping kinetics is controlled by both dissolution and precipitation kinetics. While the dissolution kinetics for carbonates and sulphate reactions are generally fairly rapid, the kinetics of aluminosilicate mineral reactions are much slower (total dissolution of these minerals can take up to thousands of years at ambient temperatures), making mineral trapping a slow process since mainly the latter are involved in CO₂ trapping processes.

For injectivity modelling the time scale of interest is the injection period (e.g., 25 years) itself and generally only the direct environment of the borehole is concerned. The main purpose of injectivity modelling is to assess if the direct environment of the well is not changing in terms of physical and chemical properties in such a way that the injection rates are affected to guarantee that the total amount can be injected under the planned circumstances. A massive injection of million tons per year can involve thermal, hydraulic, mechanical but also chemical effects around the open hole or screened section of the injector and the area around it, thereby modifying the injectivity as defined in Fig. 3. The injectivity index refers to how much fluid can be injected into an injection well at a given pressure differential between the mean injection pressure and the mean formation pressure.

Coupled modelling applications currently concern potential porosity changes due to geochemical interactions (André et al., 2007) and how this affects the injectivity. The impact of preferential flowpaths or fractured flow, and the impact of co-injecting fines are other areas of interest.

Well integrity modelling focuses on the geochemical impacts of CO₂ on the well completion itself, whether the well is the injection well built for the purpose of the CO₂ storage project or an abandoned well in case of storage in a depleted oil or gas reservoir or in deep saline aquifers penetrated by exploration and production wells. Well completions are made of a sheath of cement surrounding a casing (i.e. pipe) made of steel. The cement sheath has a role of sealing the annulus between casing and borehole walls and prevents fluid migration between formation rocks and casing. This material is also used to plug the casing in case of well abandonment. Along its life, the cement is exposed to various geological fluids (e.g.,

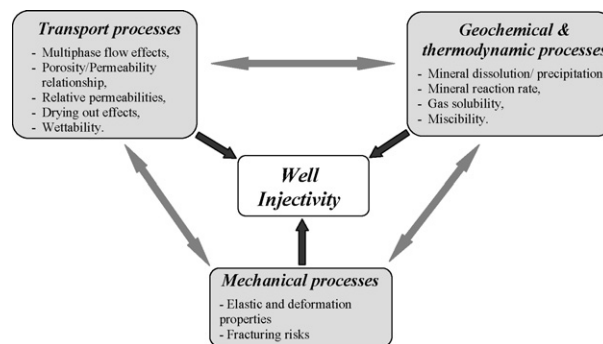

Fig. 3 – Main processes (transport, chemical and mechanical) involved by CO₂ injection: interactions between them and qualitative influence on well injectivity.

brine, CO₂-rich phase, two-component fluids). Chemical interactions occur between the brine, the gas mixture and the cement or steel. A typical reaction is the carbonation of the constitutive cement minerals (CSH¹ and portlandite²) by CO₂:

$$\text{CaO} \cdot \text{SiO}_2 \cdot \text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{CaCO}_3 + \text{SiO}_2 \cdot \text{H}_2\text{O}$$

This reaction can have consequences on cement mineralogy and porosity and indirectly on its transport and mechanical properties (see Fig. 3). An increase of permeability, diffusivity, and appearance of fissures and annular space between casing and cement sheath could create preferential paths for leaks to surface. Long time scales have to be taken into account (>1000 years) since well failure is identified as one of the major risks for release of CO₂ to the surface (Scherer et al., 2005; Celia and Bachu, 2003; Bouc et al., 2007). While the horizontal scale of interest is very small (as indicated in Fig. 2); – e.g., a well diameter can decrease with depth from 90 cm at surface to 21 cm at 4500 m depth – the vertical scale could be very large since the model has to represent the whole length (up to several thousands of metres) of the well. However, solute transport models taking into account also the vertical scale have not been published so far.

Finally, modelling of laboratory or small-scale field experiments could allow for the calibration of geochemical and solute transport models, identification of certain case specific chemical or physical parameters and short-term validation of newly developed codes since only for exceptional cases analytical solutions allowing for direct validation are available. These models are developed for the duration (at best a couple of years) and at the scale of the experiment only. Consequently, only interactions that have an impact on the short-term can be investigated.

4. Background and current status of geochemical and solute transport modelling codes

Numerical modelling of a storage site requires estimates for both the short and long-term fate of the injected CO₂. Such modelling work can be very demanding in terms of CPU time and memory and results might either be difficult to obtain or limited in terms of precision. Historically, simulations therefore generally focus either on:

- a detailed description of the geochemical fluid–rock interaction with complex mineralogical assemblages and dissolution and precipitation kinetics, while using simplified fluid flow in 1D, or not taking into account any flow aspect (batch models),
- a detailed reservoir model fluid flow in 2 or 3D with heterogeneous reservoir properties while using a simplified geochemical reactivity model.

Recent numerical modelling for CO₂ storage applications can be split into three categories: (i) hydrodynamic modelling

simulating structural, residual gas and dissolution trapping processes, (ii) geochemical modelling simulating batch geochemical reactivity (closed system without any fluid flow) and (iii) reactive transport modelling combining the two previous types of simulations and therefore providing a complete calculation over time of the amount of CO₂ trapped through structural, dissolution or mineral trapping. Reactive transport modelling is the most realistic modelling technique to quantify the long-term fate of CO₂ as well as other aspects during geological storage, but also the most challenging to perform.

4.1. Hydrodynamic modelling

Black oil reservoir simulators provide an efficient tool for performing hydrodynamic simulation to the petroleum engineering community. Using the code ECLIPSE developed by Schlumberger, Lindeberg et al. (2000) and Lindeberg and Bergmo (2003) have simulated the upward migration of the CO₂ bubble in the Utsira formation for the Sleipner project. Gradual dissolution of supercritical CO₂ in the brine increases its density with respect to the original brine. This density difference leads to convective flux within the aquifer accelerating the CO₂ bubble dissolution in the brine (Lindeberg and Bergmo, 2003). The code ECLIPSE was also used by Zhou et al. (2004) for modelling CO₂ storage in an oil reservoir for enhanced oil recovery purpose for the Weyburn project. The TOUGH family of codes developed at the Lawrence Berkeley National Laboratory (Pruess, 1987, 1991, 2004) originally for geothermal reservoir engineering, nuclear waste disposal studies and groundwater studies has been recently adapted for geological storage of CO₂ allowing simulations of CO₂ injection into deep saline aquifers (Weir et al., 1996; Pruess and García, 2002; Xu et al., 2003). A code intercomparison study has been carried out to evaluate discrepancies between different simulators using different test problems associated with CO₂ injection (Pruess et al., 2004).

Gas mixture modelling has been more recently incorporated in hydrodynamic modelling in order to provide simulations considering injection of CO₂ in gas reservoirs containing methane. Once again, compositional simulators used in the petroleum industry provide the more detailed modelling work. Carbon dioxide injection into natural gas reservoirs for combining storage with enhanced gas production has been simulated in the case of K12B site in the North Sea, the Netherlands (Van der Meer et al., 2004; Audigane et al., in press) using the black oil simulator SIMED developed by the CSIRO Petroleum (Australia) and also an adapted version of TOUGH2 to model the gas mixture of CH₄ and CO₂ (Oldenburg and Benson, 2002).

4.2. Batch geochemical modelling

Batch geochemical modelling provides an estimate of the geochemical fluid–rock interactions occurring within the formation when brine is saturated with CO₂. During batch modelling no flow is taken into account (0 dimensions). Based on a given mineral assemblage and the initial speciation of the aqueous phase enriched in dissolved CO₂, mineral dissolution and/or precipitation reactions are calculated and controlled

¹ CSH: Calcium Silicate Hydrate or CaO·SiO₂·H₂O.

² Portlandite: Ca(OH)₂.

with a kinetic rate. Changes in porosity due to mineral volume changes are calculated. The first batch modelling studies with CO₂ were published by Gunter et al. (1997). Gaus et al. (2004) presented a long-term batch geochemical study of two natural CO₂ analogues at Montmiral (France) and Messokampos (Greece) using the PHREEQC code developed by the USGS (Parkhurst and Appelo, 1999). At Montmiral, it was shown that the 3.8% porosity increase that can possibly be attributed to CO₂ related reactivity requires that sediments have been flushed intensively with CO₂-rich pore waters (open system) and that a flow regime in the reservoir must have been in place at a certain point in the reservoir's geological history. Pruess et al. (2001) and Xu et al. (2004) have presented long-term batch geochemical modelling of mineral trapping in deep aquifers through carbonate mineral precipitation.

4.3. Reactive transport modelling

Batch geochemical modelling is ideal when modelling laboratory batch experiments. However, it becomes limited when considering injection of CO₂ in a geological storage formation as hydrodynamics play a dominant role in the different trapping processes. The code TOUGHREACT is an enhancement of the multiphase fluid and heat flow code TOUGH2 to reactive transport (Xu and Pruess, 2001). Its last version (Xu et al., 2006), is able to model supercritical CO₂ injection in a reservoir by considering hydraulic processes, thermal variations and chemical phenomena. Both dissolution and precipitation processes are integrated in this code with a feedback on porosity and permeability changes. Considering a two-phase system (supercritical CO₂ and brine), Xu et al. (2005) simulated with TOUGHREACT a 1D vertical reactive transport model considering CO₂ geologic storage within a sandstone–shale system. The very detailed mineralogical assemblage used in the study is representative of the Frio Formation in the Gulf Coast sedimentary basin. Xu et al. (2003) presented another 1D horizontal model of CO₂ injection in deep arenaceous formations of U.S. Gulf Coast. In this case, the mesh geometry is radial with one layer and with a constant porosity and permeability field. A detailed mineralogy was selected representative of the Gulf Coast formations. Porosity modification due to simulated chemical reactivity was estimated for residence times of up to 10,000 years. André et al. (2007) have used TOUGHREACT to simulate fluid rock interactions during CO₂ injection for dry-out effects. They simulated complete liquid phase vaporization near the well where the salinity and overall mineralisation of the brine (high ionic strengths) becomes very high so that conventional geochemical models become unsuitable. Other models, next to the TOUGH family, that are capable of incorporating these conditions are the SIMUSCOPP code (Le Thiez et al., 1996) and the STOMP code (White and Oostrom, 2006) as pointed out in Pruess et al. (2002). Obi and Blunt (2006) have presented a 3D model of CO₂ storage into a deep North Sea aquifer using streamline-based simulation using a rate-limited precipitation reaction. Lagneau et al. (2005) have simulated the injection of CO₂ into the Dogger (Paris Basin) deep saline aquifer using the reactive transport code HYTEC which does not consider two-phase flow and therefore only the dissolved part of the injected carbon dioxide is simulated. Johnson et al.

(2001, 2004) have simulated CO₂ injection at Sleipner, North Sea for a period of 20 years with 10 years of CO₂ injection. They developed a software package based on the codes NUFT for the reactive transport part, and SUPCRT92 and GEMBOCHS for the geochemical and thermodynamics/kinetic databases (Nitao, 1998; Johnson et al., 1992; Shock, 1998; Johnson and Lundeen, 1994). In a similar approach, Audigane et al. (2006, 2007) have presented a 2D axial model to simulate CO₂ injection at Sleipner using TOUGHREACT. In further work Audigane et al. (in press) modelled two 3D models of the CO₂ injection at the depleted gas reservoir field K12B, North Sea. One was performed with the code TOUGHREACT considering the gas phase as pure CO₂, and the second simulation is performed using the code TOUGH2/EOS7C taking into account the CO₂/CH₄ mixture but without any geochemical reactivity. White et al. (2001, 2005) have developed the reactive transport code CHEMTOUGH which is another adaptation of TOUGH2 for reactive transport modelling using a fully coupled approach for solving hydrodynamics and geochemical reactivity equations (Yeh and Tripathi, 1991). Nghiem et al. (2004) have developed and used the commercial code GEM-GHG which is a combination of a black oil simulator and a geochemical batch code, to present 1D, 2D and 3D simulations considering convective and dispersive flows, as well as calculating phase equilibrium for reactions between the oil, gas and aqueous phases, and chemical equilibrium and kinetic dissolution and precipitation reactions between minerals. A specific method for solving simultaneously fluid flow and geochemical equations is presented. In the very few papers that consider that the injected CO₂ stream does not consist of pure CO₂, Ozah et al. (2005) simulated the injection of a gas mixture consisting of CO₂ and H₂S, while Knauss et al. (2005), Xu et al. (2007) and Palandri and Kharaka (2005) evaluated the impact of co-injecting H₂S and/or SO₂.

5. Reliability and the integration of geochemical modelling data

While modelling codes are increasingly capable of incorporating specific geochemical interactions caused by CO₂ and calculation efficiencies continue to improve, the underlying data and their conceptualisation will strongly influence the quality of the model outcomes. Other factors are the kinetic descriptions, representations that facilitate multiphase flow modelling and methodologies to couple interdependent geochemical, hydrological, and geomechanical processes. This is where solute transport modelling differs significantly from pure flow or dynamic modelling, when modelling the CO₂ behaviour. Decades of reservoir modelling helped to optimise data acquisition in the field and steered experimental programmes that ultimately resulted in well-constrained reservoir models with a large predictability that can now be used for modelling CO₂ storage with relatively minor adaptations. Furthermore, some of the data acquisition techniques, such as the seismics, that are capable of monitoring supercritical CO₂ plumes (Chadwick et al., 2006) now prove extremely useful for constraining dynamic CO₂ flow models. These techniques also improve large-scale solute transport models, but on top of that, the characterisation of the chemical

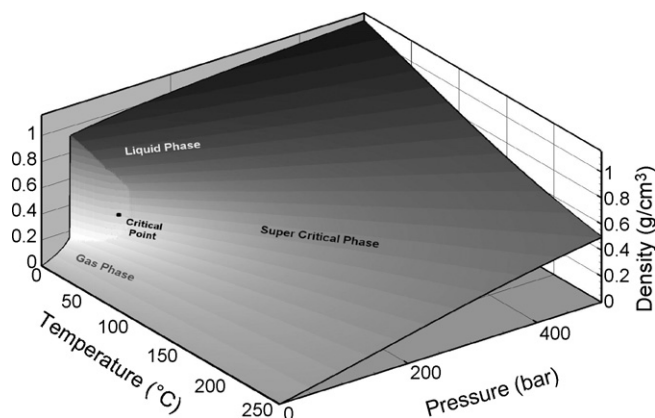

Fig. 4 – CO₂ density as a function of temperature and pressure based on the equation of state (EOS) from Duan et al. (1992).

aspects of the coupled model requires access to various types of data that are outside the domain of classic reservoir modelling and that have never been evaluated neither acquired in a similar context. Some of these required “data”—especially the requisite mathematical descriptions (e.g., solute equations of state) and underpinning reference-state thermodynamic data have been evaluated in a relevant context, namely the formation of base and precious metal deposits in low-temperature hydrothermal and high-temperature magma-hydrothermal systems. Until now, it seems that this existing knowledge is not optimally used when describing geochemical aspects of carbon storage.

Especially at large depths and high temperatures, acquiring detailed data on the mineralogy of the rocks and their heterogeneity and on the chemical composition of the brines remain extremely difficult (although recently occurring at some test sites such as Weyburn and Frio). Furthermore very few experiments characterising geochemical interactions have been performed for these high *P*–*T* conditions and in the presence of CO₂ (Rochelle et al., 2004; Bateman et al., 2005; Kaszuba et al., 2005, being rare examples). This gap in experimental knowledge that would allow the characterisation of basic parameters of CO₂ rock interactions remains a weak spot and affects the reliability of solute transport modelling considerably (see further). At the present time, reactive transport simulations do not consider any direct geochemical interactions between dry CO₂ (gaseous and supercritical) and minerals although laboratory experiments have demonstrated a strong chemical reactivity between these components for minerals constituting well cements (Jacquemet et al., 2007; Jacquemet, 2006; Regnault et al., 2005).

In the following sections, the data required for characterising geochemical reactions that need to be fed into the geochemical and coupled models are discussed. Data required for performing the dynamic flow part of the coupled models (e.g., relative permeabilities, capillary pressures) are discussed elsewhere (e.g., Juanes et al., 2006).

5.1. Properties of CO₂ and brine

When modelling the injection of CO₂ into saline aquifers, the physical and physico-chemical properties (density, solubility,

viscosity and enthalpy) of the CO₂–brine system must be included in the solute transport model. For example, the effects of CO₂ dissolved in brine and H₂O dissolved in CO₂ on the properties of both components cannot be neglected for accurate modelling since CO₂ dissolution may increase the brine’s density in such a way that density driven convective flow can be induced. A large number of equations of state (EOS), describing these properties, are currently available. But only a few indicate an accurate value for a large range of temperatures and pressures, including the discontinuity along the gas–liquid phase-change line. The Duan et al. (1992) equation of state is one of the most advanced and covers the whole pressure and temperature domain relevant for CO₂ storage applications (Fig. 4; example shown for CO₂ density), but at the price of numerical complexity. Most coupled models therefore incorporated generally an EOS valid only within a targeted range.

These equations are also used to calculate the fugacity of the CO₂ which determines its solubility, in conjunction with an aqueous model that will account for the salting out effect (Fig. 5).

Furthermore for correct chemical modelling of brines with high salinities the Pitzer formalism (Pitzer, 1973, 1991) should be applied to accurately describe these aqueous solutions. The Pitzer formalism is applied only in a few geochemical codes and rarely in solute transport codes (as in Zhang et al., 2005). Generally, ion association models such as Debye–Huckel, Davies, b-dot models, suitable for dilute solutions only are applied. Fig. 6 shows the dissolution of the carbonate calcite and highlights the error induced by the use of models only suited for dilute solutions (Davies, b-dot). This figure also shows that at high *P*_{CO₂}, even starting from pure water, the CO₂–HCO₃[–]–Ca²⁺–H⁺ system behaviour is not well calculated with such models (although temperature correction might also play a role).

Kervévan et al. (2005) summarized the relative weight of the different corrections that must be applied to the calculation of CO₂ solubility and mineral equilibrium. This showed that the corrections with respect to the fugacity and the salting out effect are the most important for CO₂ solubility calculation, while an adequate aqueous model is necessary for water–rock interaction modelling. Unfortunately, this approach is

Fig. 5 – Concentration of dissolved CO₂ (in mol/kg water) as a function of temperature and pressure in pure water (left) and in a 200 g/l brine (right) as derived from the Duan and Sun (2003) model.

numerically less efficient and there is a lack of data concerning the behaviour of some chemical elements, especially at high temperature. For the time being, only few thermal-hydraulic-chemical codes use this chemical approach, even if some codes are under development (Zhang et al., 2005, 2006).

While the required models exist for the CO₂-brine system, there is currently an important absence of data for the integration of other gaseous compounds in the gas phase, that might be co-injected (e.g., O₂, N₂, NO, SO₂, H₂S), beyond the broad assumption of ideal mixing.

5.2. Selection of mineralogical compositions and their thermodynamic characteristics

Access to detailed mineralogical data when assessing the impact of geochemical reactions is crucial, and the selection of the primary and secondary mineral assemblages is critical in this type of simulations (Zhu and Burden, 2001). Even detailed mineralogical descriptions of a rock do not necessarily permit its accurate representation in the geochemical model owing to potential gaps in the requisite thermodynamic/kinetic databases. Especially in the case of solid solutions or clay minerals, where the exact composition and thermodynamic properties

are seldom sufficiently known, this proves difficult. An example of the impact of selecting different compositions of a plagioclase solid solution is described in Gaus et al. (2005). The selection of the secondary minerals is no less sensitive. Secondary minerals are minerals which precipitate as a consequence of geochemical reactions caused by CO₂ and which are not present initially. A pragmatic way of selecting secondary minerals starts with a thermodynamic model at the equilibrium state, which permits identification of potential dominant reactions. But it cannot be excluded that intermediate minerals may form which can re-dissolve in the course of time (metastable equilibria) to precipitate as more stable minerals once the final equilibrium is reached (although in many natural systems final equilibrium is never reached). Furthermore, secondary mineral assemblages are seldom unique. Different choices, especially with respect to aluminosilicate minerals, might meet the criteria mentioned above, but might lead to different results. Certain minerals assumed to be capable of trapping CO₂, such as dawsonite, are included in many models but have only very recently been characterised (Carey et al., 2006; Bénézech et al., 2007) and it remains unclear if they will function as a carbon trap in real cases (Hellevang et al., 2005). Furthermore, only in some cases complex heterogeneous mineral distributions can be represented by average mineral properties to simplify reactive transport calculations (Glassley et al., 2002), although assuming average mineral properties is currently common practice because of computational limitations.

5.3. Kinetic data and rate laws

When modelling geochemical reactions for CO₂ storage purposes, reaction kinetics generally have to be included in order to obtain a reliable outcome (Gaus et al., 2005). Reaction kinetics vary over a large range depending on the type of reaction. Some reactions can be extremely slow, comparable to the geological scale, while other reactions reach equilibrium conditions after a couple of hours or even less. To model the evolution of the geochemical system in time, one needs to know all the factors controlling the reaction mechanisms and their rates. Accurate data on these processes are very difficult to acquire for complex systems. Typically, the study of complex system starts with a thermodynamic model at the equilibrium state. This highlights the potential occurrence of

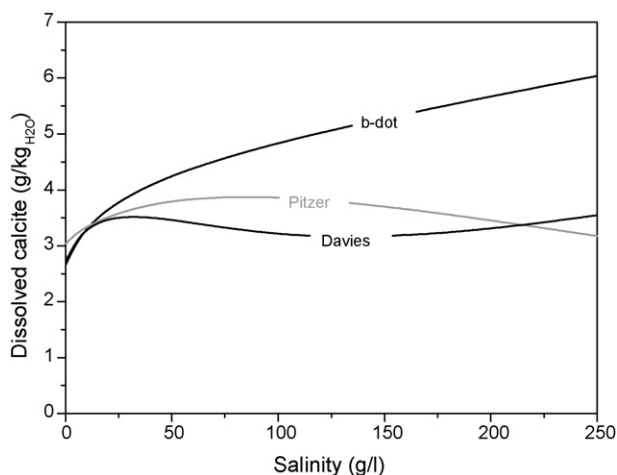

Fig. 6 – Amount of calcite dissolved in NaCl solutions at 60 °C under a P_{CO₂} of 100 bar calculated with different formalisms (Pitzer, Davies, b-dot).

Fig. 7 – Comparison of modelled dissolution rates for dolomite, kaolinite and albite at 25 °C based on Palandri and Kharaka (2004), Gunter et al. (2000), Xu et al. (2005), Chou et al. (1989), White et al. (2005) and Gaus et al. (2005).

dominant reactions. Subsequently precipitation and dissolution kinetic rates are introduced into the model, in order to simulate the evolution of the system in time and to describe the reaction pathways in detail. However, model results depend on the kinetic laws used and on parameters (typically “lumped parameters” representing more than one process) feeding into these laws that are not well-known, especially for the conditions relevant to CO₂ storage.

Many kinetic laws are described in the literature (Plummer et al., 1978; Pokrovsky et al., 2005; Lasaga et al., 1994). The kinetic law mostly used in geochemical modelling applied to the storage of CO₂ is a simplified law from Lasaga et al. (1994) considering that for many minerals the kinetic rates can be summed from three mechanisms: neutral (nu), acidic (H) and basic (b):

$$r_m = \pm A_m (k_T^{nu} + k_T^H a_H^{n_H} + k_T^b a_b^{n_b}) \left(\frac{1 - Q}{K} \right)$$

Where r is the dissolution rate, A_m is the reactive surface area, a_H is the proton activity, a_b is the base activity, n_H and n_b are the power for the acid and base activity, Q is the ionic activity product, K is the equilibrium constant. The basic mechanism depends on activities of the ions H⁺ or OH[−] according to the applied law or on the CO₂ pressure or carbonates activities for carbonate minerals. The largest effect of CO₂ on the dissolution rates is for carbonate minerals. The activities of the ions H⁺ and if included also OH[−] and P_{CO_2} associated with k^H or k^b are usually raised to the power of one ($n_H = n_b = 1$), but other values have been observed experimentally, especially at ambient temperatures (Palandri and Kharaka, 2004; Chou et al., 1989). All three mechanisms are rarely included in geochemical modelling applied to CO₂ storage (exceptions are Xu et al., 2006; André et al., 2007) especially because pH environments for CO₂ storage environments are generally assumed to be acidic due to the dissolution of CO₂. Some authors consider only the neutral mechanism (White et al., 2005; Zerai et al., 2006) or the acidic mechanism (Gaus et al., 2005; Lagneau et al., 2005) while some others consider both neutral and acidic mechanisms (Xu et al., 2005; Gunter et al., 2000). Until recently, the almost complete absence of experimental precipitation rates in the literature has led to the fact that precipitation rates are set equal to dissolution rates in coupled models although it is demonstrated that the precipitation rates of some minerals such as alteration minerals can be slow. Minerals do not

immediately crystallize out of supersaturated solution even in the presence of nucleation seeds (Lasaga et al., 1994).

Dissolution rate data are available from a variety of sources reporting kinetic rate constants (a recent compilation is made in Palandri and Kharaka, 2004). The constants are measured at various temperatures, pressures and CO₂ partial pressures and for brine composition different than those generally applicable to a CO₂ storage context. These conditions have an important impact on the rate itself as demonstrated for the CO₂ sensitive mineral labradorite in Carroll and Knauss (2005). Consequently, geochemical modellers do not use the same experimental values for the kinetic rates or for the n_H values (Xu et al., 2005; Gunter et al., 2000; Gaus et al., 2005). To illustrate this variability in dissolution rates used for geochemical modelling a comparison is made for three minerals (dolomite, kaolinite and albite) that usually dissolve and/or precipitate as a consequence of CO₂ induced interactions (Fig. 7). For dolomite, the variability can be attributed to the description of the acid mechanism. The modelled dissolution in the neutral and basic range is similar and corresponds to the experimental data and model of Chou et al. (1989), except for two authors who used dissolution rates of other minerals than dolomite as a proxy (Xu et al., 2005; White et al., 2005). The range for kaolinite is much larger; due to the large variability in experimental dissolution rates: from 10^{−13.7} to 10^{−11.6} (in mol m^{−2} s^{−1}) at pH 3 (Huertas et al., 1999; Metz and Ganor, 2001). For albite, the dissolution is controlled by the pH dependency both in an acidic and basic environment (Chou and Wollast, 1985). Although this comparison does not take into account the impact of the surface area – that is likely to be different for different media – it clearly illustrates that for one mineral the dissolution rate in the models can vary between 1 and 3 orders of magnitudes, all based on reasonable assumptions. This obviously has an impact on the simulation results as also illustrated in the following sections.

A further complicating factor when introducing kinetics is the estimation of the reactive surface area of the dissolving minerals since the dissolution rate depends on the available surface area in contact with the aqueous solution. The BET method is most used for measuring the total surface area of a mineral. However, interaction with the minerals is generally expected to occur only at selective sites at the surface (also due to the presence of grain coatings) and the difference between total surface area and reactive surface area can be between 1

and 3 orders of magnitude (White and Peterson, 1990). An alternative method to estimate the surface of the minerals, since BET measurements are only available on rare occasions, is based on the theoretical geometric surface area using average grain diameters (ranging from 1 to 200 μm ; Gunter et al., 1997; Zerai et al., 2006). This method generally underestimates the real reactive surface area since particle surfaces are rough, disrupted and porous.

The fact that in the general kinetic law the product of the reactive surface area with the kinetic rate constant is incorporated, and that both parameters are difficult to characterise, explains the large variability and therefore inherent uncertainty of geochemical and coupled models once reaction kinetics is included.

6. Main applications for geochemical and solute transport modelling (state of the art and future work)

6.1. Long-term integrity applications

Some of the first and most successful applications of coupled modelling for CO₂ storage purposes are the long-term integrity applications: medium- or long-term coupled models that take into account the geometry of the reservoir (and sometimes also the caprock) in a simplified way, and predict the ultimate fate of the injected CO₂. Especially during the last couple of years, with codes becoming more adapted, several studies appeared either in including one-dimensional (Knauss et al., 2005; Xu et al., 2005), two-dimensional (Audigane et al., 2007; Johnson et al., 2001; White et al., 2005) or three-dimensional (Nghiem et al., 2004; Le Gallo et al., 2006) transport. When geometries remain simple, it is still possible to identify dominant geochemical interactions from the calculated species concentrations and amounts of minerals dissolving and precipitating. This is shown also for two-dimensional models with a slightly more complex geology (Johnson et al., 2001, 2004; Audigane et al., 2007, *in press*). However, when the geometric complexity of the model grid and the number of layers increase, such as is the case in White et al. (2005), the identification of dominant geochemical reactions becomes increasingly difficult and the calculated results have to be accepted without being able to distil the individual geochemical reactions. In this work, a 2D vertical reactive transport model of CO₂ injection in saline reservoirs of the Colorado Plateau was developed that considers time periods of up to 100,000 years with two different meshes. A very detailed model of the hydrology of the Colorado plateau was simulated on a fine grid mesh without performing geochemistry simulations. The second mesh is coarser to provide a reactive transport simulation including complete mineralogy with plagioclase, K-feldspar, dolomite, quartz, mixed clays, illite, iron minerals and calcite. These long-term integrity models ultimately led to the consensus over the long-term behaviour as already represented in Fig. 2.

However, where different codes were applied to similar cases, results may seem different or even contradictory with respect to certain conclusions on the long-term behaviour. A clear example is the solute transport modelling performed

based on the conceptual data from the Sleipner case, the first and therefore best documented saline aquifer storage case. At Sleipner CO₂ is injected into the Mio-Pliocene Utsira Sand since 1997. Repeat seismic surveys have shown that the injected CO₂ moves, due to buoyancy effects, upward from the injection point and accumulates under the overlying cap rock (Torp and Gale, 2002). This is also confirmed by reservoir simulations which predict that CO₂ should reach the base of the thick shale layer close to the top of the Utsira Sand approximately 3 years after injection (Lindeberg et al., 2000). In order to assess the geochemical impact of this operation, Johnson et al. (2001, 2004) perform calculations over 20 years with 10 years of CO₂ injection using three conceptual 2D coupled models including the aquifer and its caprock. Some heterogeneity of the permeable sand aquifer is introduced through the presence of semi-permeable shale layers. The density difference due to CO₂ dissolution in the brine potentially causing convective flow patterns is not considered in the model, neither are the CO₂ dissolution pressure and temperature dependencies. This geometry resembles the 2D radial model published by Audigane et al. (2006, 2007) that does not include the caprock. These papers present simulations that illustrate CO₂ mass partitioning among distinct trapping mechanisms, the influence of mineral trapping on cap-rock integrity, and the geochemical reactivity associated using different mineralogies for the sand and intercalating shale layers. Frangeul et al. (2004) simulate CO₂ injection with convective flow in the Utsira Sands in 3D using the detailed flow modelling grid presented in Lindeberg et al. (2000) with a simplified mineral assemblage containing only carbonates (calcite and dolomite). In a follow-up paper, Thibeau et al. (2007) extend the number of minerals included and perform calculations using the same model but on a coarser grid. A limited sensitivity analysis on the picking of the minerals in the models to represent the reservoir mineralogy is performed. Gaus et al. (2005) model the interactions in the caprock only using a one-dimensional aqueous model. Diffusion of CO₂ through the rock is modelled by Henry's law with a constant fugacity coefficient. An overview of the coupled flow geochemical models that refer to the Sleipner case as well as their main conclusions are given in Table 1.

Although some of these results might seem contradictory, these papers show results of different modelling scenarios all referring to the same case but based on slightly different assumptions or including different parameter values. For example in the Frangeul et al. (2004) simulation only carbonate minerals are included. This simplification prevents any mineral trapping to be calculated because pure carbonate minerals are not capable of acting as primary minerals for the trapping of CO₂. Indeed, mineral trapping can only occur through the dissolution of cation donor minerals (e.g., feldspars). A complete mineralogical description is included in Thibeau et al. (2007), confirming that mineral trapping can become important and that the selection of the minerals in the model based on the mineralogical analysis from the rock is crucial. A composition based on mica's consisting predominantly of annite (an iron rich biotite) and feldspars consisting of anorthite (a calcium rich feldspar) proves far more reactive than other mineral combinations. This illustrates the need for accurate mineralogical descriptions when performing these

Table 1 – Overview of published coupled models that refer to the Utsira saline aquifer storage case at the Sleipner site, their main characteristics and findings

Reference	Geometry	Geochemistry	Simulation time	Major conclusions
Gaus et al. (2005)	1D aqueous modelling assuming diffusion in caprock only	Complete mineralogy using transition state theory reaction kinetics	3000 years	Porosity change in caprock negligible, slight decrease in porosity possible, except at the reservoir/caprock interface
Johnson et al. (2001, 2004)	2D model including reservoir, caprock, with inter aquifer clay layers	Complete mineralogy using transition state theory reaction kinetics	20 years	Intra-aquifer shales extend the volumetric extent of plume–aquifer interaction, 85% remains as SC-CO ₂ , 15% dissolves and <1% precipitates in the near field environment. Important reduction in microfracture porosity in the caprock
Frangeul et al. (2004)	3D homogeneous reservoir model	Carbonate mineralogy only. Not clear if kinetics is included	6000 years	After 6000 years 55% of the CO ₂ in dissolved form, 42% in ionic form, none precipitated
Thibeau et al. (2007)	3D homogeneous reservoir model, on a coarse grid	Complete mineralogy using transition state theory kinetics	18,000 years	Depending on the initial mineralogy, between 40% and 100% of the CO ₂ is trapped in minerals after 10,000 years
Audigane et al. (2007)	2D radial reservoir model with inter aquifer clay layers	Complete mineralogy using transition state theory kinetics	10,000 years	95% of CO ₂ dissolved in the brine, 5% taken up by minerals after 10,000 years

calculations. Although mineralogical data were available in the case of Utsira, the exact composition of clays and feldspars was not determined. This introduces uncertainty since various mineral compositions, that all perfectly match the mineralogical analysis results, can be selected in the model. The fact that the modelled porosity reduction in the caprock in Johnson et al. (2001, 2004) seems more important after 20 years than the porosity reduction after 3000 years calculated in Gaus et al. (2005) can entirely be attributed to the fact that the authors use different parameters values for the specific surface areas of the minerals. This parameter determines directly the rate at which reactions occur and is extremely difficult to measure or to estimate (see Section 5.2). The specific surface areas used in the two papers span the range of reasonably acceptable values. The only difference between the results for the porosity reduction in the caprock is the rate at which the reactions occur, not the type of the reaction or the impact on the porosity as such. Finally, the fact that in Audigane et al. (2006, 2007) the bulk of the injected CO₂ seems to be dissolved is related to the length of the simulation (10,000 years) and the fact that heterogeneities (shale layers) are taken

into account. These encourage CO₂ dissolution because the SC-CO₂ is spread out over a larger area.

The main message to retain from these 5 publications is that for CO₂ storage in the Utsira formation at Sleipner, hydrodynamic trapping will be the dominant trapping mechanism in the aquifer for a long time, mineral trapping is less important apart from the very long-term, but even then only will have a small impact on the porosity of the aquifer, that the intra-aquifer shales (and heterogeneities in general) aid the spreading of the SC-CO₂ and thus the dissolution process and that the integrity of the caprock is unlikely to be affected when no SC-CO₂ enters the caprock. At this more general level, the results of the papers reinforce each other rather than contradict.

The long-term integrity studies for which coupled models are used based on large grids representing the reservoir and caprock geometry have reached a point where the uncertainties affecting the modelled results are influenced strongly by the chemical parameters of the model such as the mineral selection, their kinetics and the reactive surface area.

6.2. Near well applications, impacts on injectivity

CO₂ injection for geological storage is a process that will take a couple of decades per site. That implies that a detailed knowledge of the reservoir and processes supposed to occur in the vicinity of the injection well during the injection phase is necessary. A massive injection of million tons per year can involve thermal, hydraulic, mechanical but also chemical perturbations around the area of well perforations of the injection well. Coupled thermal-hydraulic-chemical (THC) codes reproduce many of these processes and the interactions between them, and can aid injectivity forecasts. Although guaranteeing injectivity is a key to the viability of a CO₂ storage project, very little has been published on this topic so far. The code TOUGHREACT (Xu et al., 2006) was applied to study the behaviour of the near well during supercritical CO₂ injection (André et al., 2007). The results demonstrated that chemical processes vary according to the distance from injection well (Fig. 8). Initially, after injection started, CO₂ dissolves in the brine initially present within the reservoir and changes its chemical composition (Fig. 8, zone 2). The pH of the brine decreases and reaches 4.9–5.0, buffered by the dissolution of carbonate minerals present in the host rock. This dissolution process can, if the formed porosity is connected, improve the injectivity index of the well. However, during long-term injection, the acidification phase is followed by a desiccation phase. A CO₂ gas bubble forms around the injector pushing original water away far from the injection well (Fig. 8). Within the bubble, the medium is totally desiccated due to the dissolution of residual water in the CO₂-rich dry phase. As a consequence, zone 2, initially near the injection well, moves further away within the reservoir. The formed dry zone, centred round the injector (zone 5), constitutes a favourable site for gas–mineral interactions as demonstrated experimentally by Regnault et al. (2005). Between zone 5 (gas saturation = 1) and zone 2 (gas saturation = 0), two other zones can be distinguished. Zone 4 has very low water saturations (Fig. 8). Brine trapped in micro pores evaporates through the continuous dry CO₂ flow leading to the precipitation of certain secondary minerals (such as dissolved salts). This scaling

process is highlighted by experimental data (Kaszuba et al., 2003; Rosenbauer et al., 2005). In case of CO₂ injection, this phenomenon is to be considered: salts precipitation in the near vicinity of the injector can induce a decrease in porosity and consequently in well injectivity (André et al., 2007). This effect is salinity-dependent and it will be more pronounced in the case of high-salinity brines. Within zone 3, both gas and aqueous phases are present within the system. Because of the chemical equilibrium between the two phases, water is acidified due to water–mineral interactions. Dissolution of minerals constitute the most important process but according to reservoir conditions (T, P), precipitation of secondary minerals are not excluded. Consequently, porosity variations are expected (the decrease or the increase of porosity is dependent on the relative importance of precipitation and dissolution processes).

Although THC codes present many advantages to forecast injection flow rates or chemical processes, improvements are still necessary to describe the vicinity of the injection well in a correct way. Other parameters need to be integrated within modelling to increase the knowledge of this zone.

- All THC codes include feedback of chemical variations on porosity and permeability. But, a good description of the porous structure to describe its evolution according to injected volume, flow rates and chemical perturbations is needed. The porosity/permeability relationship constitutes a major parameter, which is reservoir-dependent.
- THC codes only consider interactions between minerals and aqueous phases. But, Regnault et al. (2005) demonstrated that mineral changes are expected in the presence of pure CO₂ phase (as transformation gypsum-anhydrite). THC codes will have to integrate the reactivity of supercritical CO₂ with minerals. This development is particularly important for the near well, where supercritical CO₂ saturation is close to one.
- To deal with saline brines, the Pitzer formalism should be applied (Pitzer, 1973, 1991) but codes including this approach are still under development (Zhang et al., 2006). Consequently, with actual code versions, some approximation and

Fig. 8 – Conceptual diagram of the reactive zones around the injection well as derived from coupled modelling (Azaroual et al., 2007). The different radii (r_1 , r_2 , r_3 , r_4) are dependent on CO₂ injection flow rate and rock properties.

Table 2 – Characteristics of the cement/CO₂ interaction modelling studies

Reference	Initial carbon concentration		Initial pH (at simulation P–T)		One- or two-phase conditions	Simulated P–T conditions	Cement domain length (m)
	Cement domain	External media	Cement domain	External media			
P	7.8×10^{-6} mol/l	1.6×10^{-2} mol/l	12.7	7.3	One-phase (brine)	(Room conditions?)	<1
J	CO ₂ -free	1.1 mol/l	8.5	4.8	One-phase (brine)	500 bar–200 °C	0.0015
B et al.	9.0×10^{-6} molal	7.0×10^{-4} molal	11.7	7.6	Two-phase (brine + CO ₂ in cement, brine only in external media)	1 bar–50 °C (cement domain), 50 bar–25 °C (external media)	2
C and L and C et al.	CO ₂ -free	P _{CO₂} = 180 bar	13	5	One-phase (brine)	180 bar–25 °C	0.25
P: Pfingsten (2002); J: Jacquemet (2006); B et al.: Burnol et al. (2006); C and L: Carey and Lichtner (2007); C et al.: Carey et al. (2007).							

under-estimations are likely, particularly in the near well environment where the presence of high salinity brines is expected during the desiccation processes (André et al., 2007).

Lastly, THC codes do not integrate the mechanical deformation involved by CO₂ injection. For the time being, fully coupled thermal–hydraulic–chemical–mechanical codes are still in the development stage. The first simulations, with external coupling between the reactive transport model and geomechanical model, give encouraging results. Johnson et al. (2005) simulated long-term cap-rock integrity as a function of geochemical and geomechanical contributions to permeability evolution using the reactive transport simulator NUFT and distinct-element geomechanical model LDEC. Rudqvist et al. (2006) modelled multi-layer systems using a coupling between TOUGH2 and FLAC3D (Itasca, 1997). Le Gallo et al. (2006) presented the long-term impact of CO₂ injection into a saline aquifer using the reactive transport model COORES and the geomechanical model ABAQUS, described in the same paper. However, these applications concern large-scale modelling and efforts should now concentrate on the near well environment.

6.3. Geochemical modelling and well integrity

To date, few studies deal explicitly with well cement degradation modelling for CO₂ storage applications. However, cement chemical degradation has been modelled many times to evaluate the material's durability in a context of nuclear waste containment (e.g., De Windt et al., 2004; Yokozeki et al., 2004; Trotignon et al., 2006). One of the main differences between simulations for carbon storage and those for nuclear waste containment applications is that while the first requires modelling at a low, acidic pH values, the latter generally takes place at high, basic pH values generating different geochemical reactions. In the few studies where cement degradation is modelled for CO₂ storage purposes, this occurs using one dimension only without including the geometry of the well itself (Jacquemet, 2006; Carey and Lichtner, 2007; Carey et al., 2007). While simulations performed by Jacquemet (2006) had the purpose of reproducing experiments, Carey and Lichtner (2007) and Carey et al. (2007) aimed to reproduce field sample degradation. Two further studies, although executed in a nuclear waste context, are further worth mentioning: Pfingsten (2002) and Burnol et al. (2006). Their work is applicable to CO₂ storage since they also modelled carbonation of cement. However, these authors did not constrain their simulations by experimental or field observations.

All the models have the same overall constructions and features:

- one-dimensional models (except Pfingsten (2002) who performed two-dimensional simulations) where a homogeneous cement domain is adjacent to an external media with sharp carbon concentration and pH gradients between the two domains (Table 2),
- a fully water-saturated cement domain (except in Burnol et al., 2006 where the cement domain is initially filled with water and gas, Table 2),

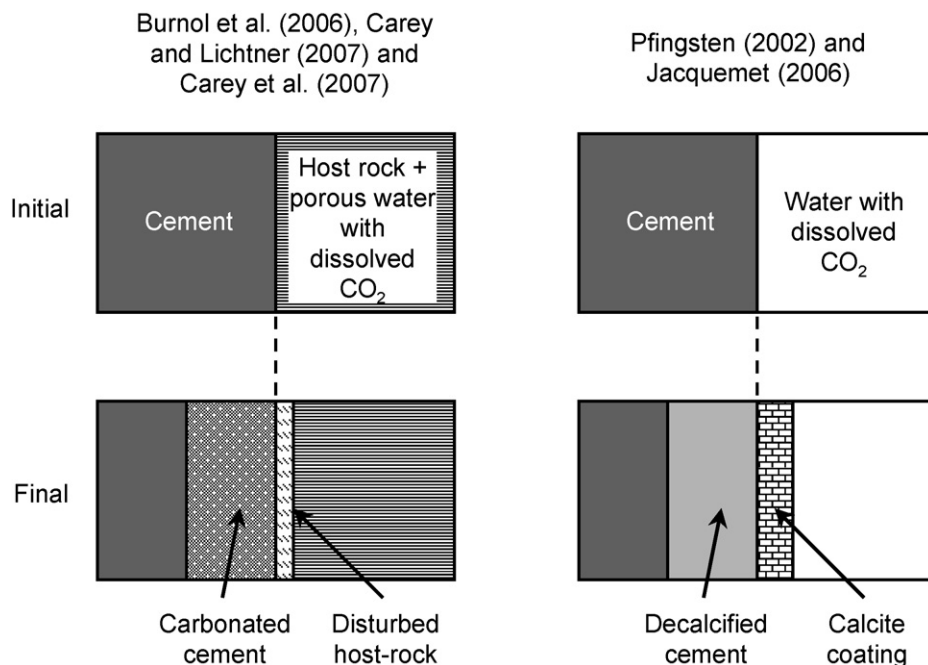

Fig. 9 – Conceptualisation of carbonation fronts of cement based on five modelling studies.

- transport of chemical species dominated by molecular diffusion.

In Carey and Lichtner (2007) and Carey et al. (2007), the external medium is composed of a clayey rock while it is composed of brine only in Pfingsten (2002) and Jacquemet (2006). The simulated P - T conditions vary from room conditions to 500 bar–200 °C and the cement domain lengths range from 1.5×10^{-3} m to 2 m.

In all the models, CO_2 and H^+ diffusive fluxes occur from the external medium through the cement, driven by the chemical gradients, and carbonation occurs. In Burnol et al. (2006), Carey and Lichtner (2007) and Carey et al. (2007), a carbonated rim (exhibiting an assemblage of carbonates plus secondary minerals) of cement is modelled (Fig. 9). Burnol et al. (2006) report also a decrease of porosity associated with this carbonated rim. In Pfingsten (2002) and Jacquemet (2006), the carbonation front is mimicked by a rim of decalcified cement (exhibiting Ca-depleted CSH) and a separate calcite coating at the surface of the cement (Fig. 9). As this coating grows, it becomes a barrier (porosity close to zero) for the incoming species (carbonates and protons) and blocks the degradation of the cement. The calcite coating can develop due to the available volume at the surface of cement that allows calcite to precipitate. This is in contrast to the three other studies where the external medium is made of rock where no such available volume allows calcite to massively precipitate.

Various research needs are identified by the authors in order to better constrain cement degradation modelling: (1) improved transport parameter characterisation (diffusivity and permeability) of well cements; (2) improved determination of thermo-kinetic parameters of well cement minerals reactions at appropriate P - T conditions; (3) evaluation of the

impact of cement heterogeneity. Pfingsten (2002) also emphasizes the need for additional data on the dependence of permeability and diffusivity on porosity since carbonation is likely to decrease porosity significantly (Thiery, 2005; Jacquemet, 2006). As it was explored by Burnol et al. (2006), future modelling should take into account the possibility of carbonation in two-phase conditions, e.g., by intrusion of gas within the cement. Regnault et al. (2005) and Jacquemet (2006) demonstrate experimentally that significant carbonation can also occur in the complete absence of brine. As mentioned before, currently reactive-transport codes do not consider gas–mineral reactions and should do so in the future. For cements, carbonation is responsible of shrinkage (Taylor, 1997; Kovler and Zhutovsky, 2006). Coupling geochemical and mechanical models could help to better understand mechanical effects of carbonation. Other reactions between other gaseous components and cement should also be taken into account. For example, SO_2 and SO_3 could potentially be co-injected with CO_2 . These gases will form dissolved sulphates (HSO_4^- , SO_4^{2-}) within formation water (under specific conditions) that are known to damage cement via the “sulphate attack” reaction. This has important deleterious physical effects like internal cracking and expansion (Taylor, 1997; Maltais et al., 2004). Carey and Lichtner (2007) modelled a sulphate attack reaction of a well cement. They reproduced the general mineral changes related to this reaction (i.e. precipitation of sulphates (ettringite, gypsum) and decalcification of CSH).

Finally, the existing studies account for relatively small-scale systems at the laboratory scale (Table 2), not taking into account the geometry of the cement sheath or the well. After up-scaling, the final goal of future well cement modelling degradation would be the prediction of CO_2 vertical flux through the cement sheath.

6.4. Calibration and validation of the geochemical and solute transport models on laboratory and field experiments

Most of the phenomena and their impact predicted by geochemical and coupled models occur over long time frames (long-term integrity modelling, injectivity modelling). For these timeframes, calibration is generally not possible since multiple year time-series with data on geochemical impact plainly do not exist. Therefore, only laboratory experiments and small-scale field studies can be used as an alternative for calibration and to verify that processes predicted by the long-term models are occurring in reality. The major drawback remains that these experiments can run at best over a couple of years and are thus not capable of reproducing slow phenomena that have an impact on the long-term only, especially when conducted at low temperatures ($<60^\circ\text{C}$).

A series of experiments have been conducted and modelled to assess the mineral trapping capacity and porosity changes in porous media. Gunter et al. (1997) carried out batch experiments containing a mineral assemblage that reacts with CO_2 -rich solution (105°C and 90 bar). Due to slow reaction rates, the transformation of aluminosilicates is not observed but the composition of the solution changes. The geochemical model (PATHARC94; Perkins and Gunter, 1995a) helps to interpret these data, but the authors highlight potential errors as high as two orders of magnitude using reported kinetic rates which they compensated by reduced the surface area to match experimental and modelled results. In the long-term, trapping of CO_2 as calcite and siderite occurs, but to understand the processes more detail is necessary on the precipitation kinetics and the exact composition of the mineral phases (solid solution). Batch and column experiments on samples of the Midale formation at Weyburn were assessed through thermodynamic equilibrium modelling (Azaroual et al., 2004) illustrating carbonate dissolution, precipitation of gypsum and “inhibition” of anhydrite dissolution. Observations and model interpretations helped to develop hypothesis that were subsequently included in long-term 1D PHREEQC modelling. Rosenbauer et al. (2005) carried out batch experiments reacting CO_2 with natural and synthetic brines in the presence or absence of limestone and plagioclase-rich arkosic sandstone at reservoir conditions (120°C and 300 bar). The authors used SOLMINEQ99 (Kharaka et al., 1988) to calculate in situ carbonate species, pH and the saturation index of individual minerals. The authors concluded that compositional, mineralogical and porosity changes in the aquifer fluid and rock are dependent on initial brine composition especially with respect to dissolved calcium and sulphate concentrations. Palandri and Kharaka (2005) studied the interaction of CO_2 – SO_2 with hematite under reservoir conditions (150°C and 300 bar) and concluded that reactions are kinetically determined resulting in concentrations far from equilibrium and that the precipitation of metastable phases plays an important role. According to the authors, the predictions based on computer simulations are largely confirmed by experimental results. The CO_2 and SO_2 mixture reduces Fe^{III} in hematite and dissolves it as Fe^{II} which subsequently precipitates as siderite and pyrite and/or FeS -am. Shiraki and Dunn (2000) examined water rock interaction through core-flooding experiments under reservoir conditions (80°C and 166 bar). The solution and CO_2 are

injected into a core sample from the Tensleep Formation in the Oregon oil field. Three major reactions were identified (1) dissolution of dolomite, (2) alteration of K-feldspar to form kaolinite that reduces the permeability, (3) precipitation or dissolution of anhydrite according to the salinity of the injection solution. These reactions are reproduced using the SOLMINEQ88 (Kharaka et al., 1988) code based on speciation and mineral saturation index calculations. Bateman et al. (2005) provided a well-constrained laboratory experiment of long duration whereby a synthetic mineral composition reacts with CO_2 -rich fluids. The model predictions performed using their internal coupled code PRECIP (British geological Survey) tend to overestimate the reactivities compared with the experimental results. Certain minerals phases that are predicted to precipitate in large quantities are not observed in the experimental system. These differences between the model and the observations highlight the need for thermodynamic and kinetic data with respect to CO_2 induced interactions at relevant P–T conditions, especially with respect to the precipitation of secondary minerals.

The bulk of these experiments have been designed in the first place to observe geochemical interactions and draw conclusions from the observations rather than calibrate solute transport models. This has as a consequence that generally complex mineralogies are selected and that many interacting geochemical reactions occur. This requires many (largely unknown) parameters (such as kinetic constants and reactive surface areas) to be introduced in the models resulting in too many degrees of freedom. For the purpose of calibrating and refining reactive transport models, specific experiments must be designed that focus on a minimal number of fluid–mineral reactions and dissolution/precipitation processes (e.g., Johnson et al., 1998).

Experimental work has also been conducted on dissolution of carbonate rocks due to the injection of acids. Dissolution due to the CO_2 injection of predominantly carbonates could weaken the injection zone. The difficulty is in the modelling of the formation and the propagation of the dissolution patterns (wormholes) which results from an instability similar to viscous fingering. Several authors (Golfier et al., 2001; Pomès et al., 2001) point out the need for developing a numerical code that accounts for wormhole formation at the Darcy scale. Golfier et al. (2001) built a 2D numerical simulator which calculates the dissolution pattern in a core. This code considers the physics at the pore-scale. The flow equation takes into account Darcy flow in the matrix and Stokes law in the wormhole. Based on experimental results, the model provides relations on wormhole propagation rate depending on reservoir properties and injection conditions. It might be possible to integrate these equations in a near well-bore simulator for a better design of the acidizing impacts in carbonates. Pomès et al. (2001) investigate this approach to build the up-scaled model for reservoir simulations.

Small-scale field studies that include geochemical monitoring and verification through modelling have been rare so far, the Frio Formation injection (Kharaka et al., 2006) and the Weyburn site (Emberley et al., 2005) being the first. The first study clearly demonstrated that reactions that have been predicted by geochemical models before, such as pH buffering after the dissolution of CO_2 through the dissolution of

carbonates and dissolution of iron from iron-oxides at low pH values, occur in reality. However, the density of the geochemical data and the heterogeneity of the system does not allow for a calibration “*sensu strictu*” of the geochemical model.

7. Conclusions and outlook

Reactive transport modelling is an essential tool for the analysis of coupled physical, chemical and biological processes in earth systems. One of its more recent application domains is that of carbon dioxide geological storage, whereby the impact of geochemical reactions induced by CO₂ and its feedback on physical properties has to be assessed. This has to occur at great depth, at high temperatures and pressures, conditions that traditionally belong to the domain of reservoir geology, where especially short, medium, and long-term geochemical impacts rarely received much attention. During the last 10 years geochemical and coupled geochemical and flow modelling made significant progress evolving from simple geochemical batch models to three-dimensional fully coupled models. Four main application domains are identified each having a different purpose with respect to analysing the geochemical impact of CO₂ storage and each facing its own challenges.

Long-term integrity modelling predicts the final fate of the CO₂ injected in terms of structural trapping, residual gas trapping, solubility trapping and mineral trapping at the reservoir scale. Currently simplified (with respect to classic reservoir models) fully coupled 3D models taking into account a reasonable level of heterogeneity are being developed allowing for such a complex assessment. Weaknesses remain in the identification of dominant geochemical reactions (initial mineral selection) and poor knowledge of reaction kinetics, making it difficult to attribute an adequate time scale to the occurrence of the trapping processes. A further challenge for long-term integrity modelling will be making the step from modelling only the reservoir environment toward scenario modelling, that will be part of the risk assessment. Generally, for scenario modelling not only the reservoir has to be taken into account, but also the overburden. In most cases, the overburden is likely to consist of a sequence of cap rocks, saline aquifers and potable aquifers, probably partly cross-cut by faults, fault systems and wells. Including this geological complexity will induce significant numerical difficulties, especially when also geomechanical effects have to be taken into account.

Injectivity modelling assesses the geochemical impact in the direct environment of the borehole, to make sure that injection takes place as planned. Coupled modelling in this area thus focuses on a smaller spatial scale (direct borehole environment) and shorter timeframe (injection period) than long-term integrity modelling. Here the intense flushing of the reservoir rock around the injector with large quantities of dried SC-CO₂ can cause desiccation of the remaining brine in the pore space, leading to substantial precipitation of salts and sulphate minerals, blocking the pores, and diminishing injectivity. On the other hand, carbonate dissolution by the acidified brine could cause porosity and permeability to increase. Both precipitation and dissolution can cause geomechanical effects taking into account the large pressure

variations that can occur close to the injector. Especially in this area of modelling the need for coupled models, linking flow, chemistry, geomechanics and thermal processes is large. First attempts have started but a long way still lies ahead. Another challenge is the correct modelling of dissolution and precipitation reactions in extremely concentrated brines for which ion interaction models have to be applied (e.g., Pitzer approach) that are currently under development (as part of pure geochemical codes), but are rarely integrated in coupled codes at the moment.

Well integrity modelling goes to the heart of the risk assessment of a CO₂ storage project since wells (both newly drilled ones as well as abandoned wells) are identified as a main concern with respect to leakage. Currently coupled flow and geochemical modelling in this area is essentially performed to elucidate cement interactions with CO₂ at the laboratory scale. Modelled results confirm the occurrence of the experimentally and on-field observed carbonation reaction that can potentially reduce porosity and permeability. Since the mineralogy of cements is fundamentally different from that of geological materials, appropriate thermo-kinetic data at relevant P–T conditions are needed. This currently presents a serious limitation to model outcomes. Up-scaling of the results and taking into account the well geometry and potential mechanical effects of carbonation remain challenges in this application domain.

Finally, *modelling of laboratory and small field scale experiments* could aid the calibration of coupled geochemical models – although only for short-term phenomena, taking into account the limited duration of experiments – before applying the models to longer time scales. However, experiments are generally designed to observe processes rather than to perform a calibration. Furthermore, experiments are generally set up at conditions and using materials as close as possible to the geological reality (using heterogeneous rocks or complex brine compositions for example) to reproduce geochemical reactions and their impacts as they occur in the field. Although this type of experiments allows to verify if geochemical reactions predicted by the models occur in reality, they do not allow for a calibration of the model “*sensu strictu*” since too many parameters are involved and a unique interpretation is generally not possible. Specific experiments aimed at the calibration of one single reaction (e.g., pure albite dissolution generating dawsonite precipitation), at conditions relevant for CO₂ storage, seem necessary. These experiments, specifically designed to apply and test the models, would allow for a more rigorous model calibration.

All four of the application domains are essential when it comes to assessing the impact of CO₂ storage and prove that geochemistry is an intrinsic part of it that cannot be neglected. One of the main challenges when applying coupled modelling is that for the relevant temperature and pressure conditions and brine compositions, calculations have to be made outside the validity ranges of certain concepts that are generally integrated in geochemical models (e.g., ion association models, solubility calculations) and that are based on parameters values that were determined for different conditions. On top of that, it is difficult and expensive to acquire detailed geochemical parameters at high pressures and temperatures. As a consequence, insufficient accurate input

data exist that are directly suitable for longer term geochemical modelling of CO₂ storage applications. This induces large uncertainties in model outcomes, especially when compared to uncertainty ranges generally encountered in pure physical (reservoir) modelling. Experimental work in specific CO₂ storage contexts is needed to create reliable input parameters for coupled modelling. This lack of basic thermodynamical and kinetic data (especially for precipitating minerals) is a recurring issue in each of the four application domains.

New areas for geochemical and solute transport modelling in the CO₂ storage domain are emerging. The need to investigate the link between flow, geochemistry and geomechanics is illustrated on several occasions. The possibility of co-injecting other gaseous compounds – present in the gas stream as a result of the capture process – together with CO₂ is currently considered for economic reasons. The chemical reactivity of each of these compounds (e.g., O₂, N₂, NO, SO₂, H₂S) has to be evaluated and their mutual impact modelled, especially since some of them are far more reactive than CO₂. This will require an important research effort with respect to the development of adequate equations of state (EOS) and solubility models, an effort that has only just started. Pore-scale modelling applied to CO₂ storage, describing the geochemical behaviour at the pore-scale and clarifying the link between dissolution–precipitation processes and porosity–permeability relations, is another area that is just emerging.
